How big is my node?

- Basic question:** how 'important' are specific nodes and edges in a network?
- An important node or edge might:**
 - handle** a relatively large amount of the network's traffic (e.g., cars, information);
 - bridge** two or more distinct groups (e.g., liason, interpreter);
 - be a **source** of important ideas, knowledge, or judgments (e.g., supreme court decisions, an employee who 'knows where everything is').
- So how do we quantify such a slippery concept as importance?
- We generate ad hoc, reasonable measures, and examine their utility ...

Centrality

- One possible reflection of importance is **centrality**.
- Presumption is that nodes or edges that are (in some sense) in the middle of a network are important for the network's function.
- Idea of centrality comes from social networks literature^[7].
- Many flavors of centrality ...
 - Many are topological and quasi-dynamical;
 - Some are based on dynamics (e.g., traffic).
- We will define and examine a few ...
- (Later: see centrality useful in identifying communities in networks.)

Centrality

Degree centrality

- Naively estimate importance by **node degree**. [7]
- Doh**: assumes linearity (If node i has twice as many friends as node j , it's twice as important.)
- Doh**: doesn't take in any non-local information.

Consider a network with N nodes and m edges (possibly weighted).

Computational goal: Find $\binom{N}{2}$ shortest paths between all pairs of nodes.

Traditionally use **Floyd-Warshall** algorithm.

Computation time grows as $O(N^3)$.

See also:

- Dijkstra's algorithm for finding shortest path between two specific nodes,
- and Johnson's algorithm which outperforms Floyd-Warshall for sparse networks: $O(mN + N^2 \log N)$.

Newman (2001) [4, 5] and Brandes (2001) [1] independently derive equally fast algorithms that also compute betweenness.

Computation times grow as:

- $O(mN)$ for unweighted graphs;
- and $O(mN + N^2 \log N)$ for weighted graphs.

Closeness centrality

- Idea**: Nodes are more central if they can reach other nodes 'easily.'
- Measure average shortest path from a node to all other nodes.
- Define **Closeness Centrality** for node i as

$$\frac{N - 1}{\sum_{j, j \neq i} (\text{shortest distance from } i \text{ to } j)}.$$

- Range is 0 (no friends) to 1 (single hub).
- Unclear what the exact values of this measure tells us because of its ad-hocness.
- General problem with simple centrality measures: what do they exactly mean?
- Perhaps, at least, we obtain an ordering of nodes in terms of 'importance.'

Shortest path between node i and all others:

Consider unweighted networks.

Use **breadth-first search**:

- Start at node i , giving it a distance $d = 0$ from itself.
- Create a list of all of i 's neighbors and label them being at a distance $d = 1$.
- Go through list of most recently visited nodes and find all of their neighbors.
- Exclude any nodes already assigned a distance.
- Increment distance d by 1.
- Label newly reached nodes as being at distance d .
- Repeat steps 3 through 6 until all nodes are visited.

Record which nodes link to which nodes moving out from i (former are 'predecessors' with respect to i 's shortest path structure).

Runs in $O(m)$ time and gives $N - 1$ shortest paths.

Find all shortest paths in $O(mN)$ time

Much, much better than naive estimate of $O(mN^2)$.

Betweenness centrality

- Betweenness centrality** is based on coherence of shortest paths in a network.
- Idea**: If the quickest way between any two nodes on a network disproportionately involves certain nodes, then they are 'important' in terms of global cohesion.
- For each node i , count how many shortest paths pass through i .
- In the case of ties, divide counts between paths.
- Call frequency of shortest paths passing through node i the betweenness of i , B_i .
- Note: Exclude shortest paths between i and other nodes.
- Note: works for weighted and unweighted networks.

Newman's Betweenness algorithm: [4]

1. Set all nodes to have a value $c_{ij} = 0, j = 1, \dots$ (c for count).
2. Select one node i and find **shortest paths** to all other $N - 1$ nodes using breadth-first search.
3. Record # equal shortest paths reaching each node.
4. Move through nodes according to their distance from i , starting with the furthest.
5. Travel **back towards i from each starting node j** , along shortest path(s), adding 1 to every value of $c_{i\ell}$ at each node ℓ along the way.
6. Whenever more than one possibility exists, apportion according to total number of short paths coming through predecessors.
7. Exclude starting node j and i from increment.
8. Repeat steps 2-8 for every node i and obtain betweenness as $B_j = \sum_{i=1}^N c_{ij}$.

Important nodes have important friends:

- Define x_i as the 'importance' of node i .
- Idea: x_i depends (somehow) on x_j if j is a neighbor of i .
- Recursive: importance is transmitted through a network.
- Simplest possibility is a linear combination:

$$x_i \propto \sum_j a_{ji} x_j$$

- Assume further that constant of proportionality, c , is independent of i .
- Above gives $\vec{x} = c\mathbf{A}^T \vec{x}$ or $\mathbf{A}^T \vec{x} = c^{-1} \vec{x} = \lambda \vec{x}$.
- Eigenvector equation based on adjacency matrix ...
- Note: Lots of despair over size of the largest eigenvalue. [7] Lose sight of original assumption's non-physicality.

Newman's Betweenness algorithm: [4]

- For a **pure tree network**, c_{ij} is the number of nodes beyond j from i 's vantage point.
- Same algorithm for computing drainage area in river networks (with 1 added across the board).
- For **edge betweenness**, use exact same algorithm but now
 1. j indexes edges,
 2. and we add one to each edge as we traverse it.
- For both algorithms, computation time grows as

$$O(mN).$$

Important nodes have important friends:

- So: solve $\mathbf{A}^T \vec{x} = \lambda \vec{x}$.
- But which eigenvalue and eigenvector?
- We, the people, would like:
 1. A unique solution. ✓
 2. λ to be real. ✓
 3. Entries of \vec{x} to be real. ✓
 4. Entries of \vec{x} to be non-negative. ✓
 5. λ to actually mean something ... (maybe too much)
 6. Values of x_i to mean something (what does an observation that $x_3 = 5x_7$ mean?) (maybe only ordering is informative ...)
 7. λ to equal 1 would be nice ... (maybe too much)
 8. Ordering of \vec{x} entries to be robust to reasonable modifications of linear assumption (maybe too much)
- We rummage around in bag of tricks and pull out the Perron-Frobenius theorem ...

Perron-Frobenius theorem: [7] If an $N \times N$ matrix A has non-negative entries then:

1. A has a real eigenvalue $\lambda_1 \geq |\lambda_i|$ for $i = 2, \dots, N$.
2. λ_1 corresponds to left and right 1-d eigenspaces for which we can choose a basis vector that has non-negative entries.
3. The dominant real eigenvalue λ_1 is bounded by the minimum and maximum row sums of A :

$$\min_i \sum_{j=1}^N a_{ij} \leq \lambda_1 \leq \max_i \sum_{j=1}^N a_{ij}$$

4. All other eigenvectors have one or more negative entries.
5. The matrix A can make toast.
6. Note: Proof is relatively short for symmetric matrices that are strictly positive [6] and just non-negative [3].

Other Perron-Frobenius aspects:

- Assuming our network is **irreducible**, meaning there is only one component, is reasonable: just consider one component at a time if more than one exists.
- Irreducibility means largest eigenvalue's eigenvector has strictly non-negative entries.
- Analogous to notion of ergodicity: every state is reachable.
- (Another term: **Primitive** graphs and matrices.)

Hubs and Authorities

- So let's say we have

$$\vec{x} = c_1 A^T \vec{y} \text{ and } \vec{y} = c_2 A \vec{x}$$

where c_1 and c_2 must be positive.

- Above equations combine to give

$$\vec{x} = c_1 A^T c_2 A \vec{x} = \lambda A^T A \vec{x}.$$

where $\lambda = c_1 c_2 > 0$.

- It's all good:** we have the heart of singular value decomposition before us ...

Hubs and Authorities

- Generalize eigenvalue centrality to allow nodes to have two attributes:
 - Authority:** how much knowledge, information, etc., held by a node on a topic.
 - Hubness (or Hubosity or Hubbishness or Hubtasticness):** how well a node 'knows' where to find information on a given topic.
- Original work due to the legendary Jon Kleinberg. [2]
- Best hubs point to best authorities.
- Recursive:** Hubs authoritatively link to hubs, authorities hubbishly link to other authorities.
- More:** look for dense links between sets of 'good' hubs pointing to sets of 'good' authorities.
- Known as the **HITS algorithm** (Hyperlink-Induced Topics Search).

We can do this:

- $A^T A$ is symmetric.
- $A^T A$ is semi-positive definite so its eigenvalues are all ≥ 0 .
- $A^T A$'s eigenvalues are the square of A 's singular values.
- $A^T A$'s eigenvectors form a joyful orthogonal basis.
- Perron-Frobenius tells us that only the dominant eigenvalue's eigenvector can be chosen to have non-negative entries.
- So: linear assumption leads to a solvable system.
- What would be very good: find networks where we have independent measures of node 'importance' and see how importance is actually distributed.

Hubs and Authorities

- Give each node two scores:
 - x_i = **authority score** for node i
 - y_i = **hubtasticness score** for node i
- As for eigenvector centrality, we connect the scores of neighboring nodes.
- New story I: a good authority is linked to by good hubs.
- Means x_i should increase as $\sum_{j=1}^N a_{ji} y_j$ increases.
- Note:** indices are ji meaning j has a directed link to i .
- New story II: good hubs point to good authorities.
- Means y_i should increase as $\sum_{j=1}^N a_{ij} x_j$ increases.
- Linearity assumption:

$$\vec{x} \propto A^T \vec{y} \text{ and } \vec{y} \propto A \vec{x}$$

Nutshell:

- Measuring centrality is well motivated if hard to carry out well.
- We've only looked at a few major ones.
- Methods are often taken to be more sophisticated than they really are.
- Centrality can be used pragmatically to perform diagnostics on networks (see structure detection).
- Focus on nodes rather than groups or modules is a homo narrativus constraint.
- Possible that better approaches will be developed.
