Social Contagion

Two focuses for us

- Widespread media influence
- Word-of-mouth influence

We need to understand influence

- Who influences whom? Very hard to measure...
- What kinds of influence response functions are there?
- Are some individuals super influencers? Highly popularized by Gladwell [12] as 'connectors'
- The infectious idea of opinion leaders (Katz and Lazarsfeld) [19]

From a 2013 Believer Magazine interview with Maurice Sendak

BLVR: Did the success of Where the Wild Things Are ever feel like an albatross?

MS: It's a nice book. It's perfectly nice. I can't complain about it. I remember Herman Melville said, "When I die no one is going to mention Moby-Dick. They're all going to talk about my first book, about ***ing maidens in Tahiti." He was right. No mention of Moby-Dick then. Everyone wanted another Tahitian book, a beach book. But then he kept writing deeper and deeper and then came Moby-Dick and people hated it. The only ones who liked it were Mr. and Mrs. Nathaniel Hawthorne. Moby-Dick didn't get famous until 1930.

Why do things spread socially?

- Because of properties of special individuals?
- Or system level properties?
- Is the match that lights the fire important?
- Yes. But only because we are storytellers: *homo narrativus*.
- We like to think things happened for reasons ...
- Reasons for success are usually ascribed to intrinsic properties (examples next).
- Teleological stories of fame are often easy to generate and believe.
- System/group dynamics harder to understand because most of our stories are built around individuals.
- Always good to examine what is said before and after the fact ...

Social contagion models

Thresholds

- Basic idea: individuals adopt a behavior when a **certain fraction of others** have adopted
- 'Others' may be everyone in a population, an individual's close friends, any reference group.
- Response can be probabilistic or deterministic.
- Individual thresholds can vary
- Assumption: order of others' adoption does not matter... (**unrealistic**).
- Assumption: level of influence per person is uniform (**unrealistic**).

Social Contagion

Some possible origins of thresholds:

- Inherent, evolution-devised inclination to coordinate, to conform, to imitate.^[1]
- Lack of information**: impute the worth of a good or behavior based on degree of adoption (social proof)
- Economics: **Network effects** or **network externalities**
 - Externalities = Effects on others not directly involved in a transaction
 - Examples: telephones, fax machine, TikTok, operating systems
 - An individual's utility increases with the adoption level among peers and the population in general

Threshold models

Example of single stable state model:

Many years after Granovetter and Soong's work:

- “A simple model of global cascades on random networks”
D. J. Watts. Proc. Natl. Acad. Sci., 2002 [27]
- Mean field model → network model
- Individuals now have a limited view of the world

We'll also explore:

- “Seed size strongly affects cascades on random networks” [14]
Gleeson and Cahalane, Phys. Rev. E, 2007.
- “Direct, physically motivated derivation of the contagion condition for spreading processes on generalized random networks” [10] Dodds, Harris, and Payne, Phys. Rev. E, 2011
- “Influentials, Networks, and Public Opinion Formation” [28]
Watts and Dodds, J. Cons. Res., 2007.

Snowballing

First study random networks:

- Start with N nodes with a degree distribution P_k
- Nodes are randomly connected (carefully so)
- Aim: Figure out when activation will propagate
- Determine a **cascade condition**

The Cascade Condition:

- If one individual is initially activated, what is the probability that an activation will spread over a network?
- What features of a network determine whether a cascade will occur or not?

Threshold models

Chaotic behavior possible [17, 16, 9, 18]

Threshold model on a network

All nodes have threshold $\phi = 0.2$.

Example random network structure:

- $\Omega_{crit} = \Omega_{vuln} =$ critical mass = global vulnerable component
- $\Omega_{trig} =$ triggering component
- $\Omega_{final} =$ potential extent of spread
- $\Omega =$ entire network

$$\Omega_{crit} \subset \Omega_{trig}; \Omega_{crit} \subset \Omega_{final}; \text{ and } \Omega_{trig}, \Omega_{final} \subset \Omega.$$

Threshold models—Nutshell

Implications for collective action theory:

- Collective uniformity \nRightarrow individual uniformity
- Small individual changes \Rightarrow large global changes
- The stories/dynamics of complex systems are conceptually inaccessible for individual-centric narratives.
- System stories live in left null space of our stories—we can't even see them.
- But we happily impose simplistic, individual-centric stories—we can't help ourselves ↗.

Threshold model on a network

- Interactions between individuals now represented by a network.
- Network is **sparse**.
- Individual i has k_i contacts.
- Influence on each link is **reciprocal** and of **unit weight**.
- Each individual i has a fixed threshold ϕ_i .
- Individuals repeatedly poll contacts on network.
- Synchronous, discrete time updating.
- Individual i becomes active when fraction of active contacts $\frac{a_i}{k_i} \geq \phi_i$.
- Individuals remain active when switched (no recovery = SI model).

Snowballing

Follow active links

- An active link is a link connected to an activated node.
- If an infected link leads to **at least 1 more infected link**, then **activation spreads**.
- We need to understand which nodes can be activated when only one of their neighbors becomes active.

The most gullible

Vulnerables:

- We call individuals who can be activated by just one contact being active **vulnerables**
- The vulnerability condition for node i :

$$1/k_i \geq \phi_i$$

- Which means # contacts $k_i \leq \lceil 1/\phi_i \rceil$
- For global cascades on random networks, must have a *global cluster of vulnerables* [27]
- Cluster of vulnerables = critical mass**
- Network story: 1 node \rightarrow critical mass \rightarrow everyone.

Cascade condition

Putting things together:

- Expected number of active edges produced by an active edge:

$$R = \underbrace{\sum_{k=1}^{\infty} (k-1) \cdot \beta_k \cdot \frac{kP_k}{\langle k \rangle}}_{\text{success}} + \underbrace{0 \cdot (1 - \beta_k) \cdot \frac{kP_k}{\langle k \rangle}}_{\text{failure}}$$

$$= \sum_{k=1}^{\infty} (k-1) \cdot \beta_k \cdot \frac{kP_k}{\langle k \rangle}$$

Cascades on random networks

- Cascades occur only if size of max vulnerable cluster > 0 .
- System may be 'robust-yet-fragile'.
- 'Ignorance' facilitates spreading.

Cascade condition

Back to following a link:

- A randomly chosen link, traversed in a random direction, leads to a degree k node with probability $\propto kP_k$.
- Follows from there being k ways to connect to a node with degree k .
- Normalization:

$$\sum_{k=0}^{\infty} kP_k = \langle k \rangle$$

- So

$$P(\text{linked node has degree } k) = \frac{kP_k}{\langle k \rangle}$$

Cascade condition

So... for random networks with fixed degree distributions, cascades take off when:

$$\sum_{k=1}^{\infty} (k-1) \cdot \beta_k \cdot \frac{kP_k}{\langle k \rangle} > 1.$$

- β_k = probability a degree k node is vulnerable.
- P_k = probability a node has degree k .

Cascade window for random networks

- 'Cascade window' widens as threshold ϕ decreases.
- Lower thresholds enable spreading.

Cascade condition

Next: Vulnerability of linked node

- Linked node is **vulnerable** with probability

$$\beta_k = \int_{\phi'_*=0}^{1/k} f(\phi'_*) d\phi'_*$$

- If linked node is **vulnerable**, it produces $k-1$ new outgoing active links
- If linked node is **not vulnerable**, it produces **no** active links.

Cascade condition

Two special cases:

- (1) Simple disease-like spreading succeeds: $\beta_k = \beta$

$$\beta \cdot \sum_{k=1}^{\infty} (k-1) \cdot \frac{kP_k}{\langle k \rangle} > 1.$$

- (2) Giant component exists: $\beta = 1$

$$1 \cdot \sum_{k=1}^{\infty} (k-1) \cdot \frac{kP_k}{\langle k \rangle} > 1.$$

Cascade window for random networks

All-to-all versus random networks

Determining expected size of spread:

- Randomly turn on a fraction ϕ_0 of nodes at time $t = 0$
- Capitalize on local branching network structure of random networks (again)
- Now think about what must happen for a specific node i to become active at time t :
 - $t = 0$: i is one of the seeds (prob = ϕ_0)
 - $t = 1$: i was not a seed but enough of i 's friends switched on at time $t = 0$ so that i 's threshold is now exceeded.
 - $t = 2$: enough of i 's friends and friends-of-friends switched on at time $t = 0$ so that i 's threshold is now exceeded.
 - $t = n$: enough nodes within n hops of i switched on at $t = 0$ and their effects have propagated to reach i .

Expected size of spread

Notes:

- Calculations are possible if nodes do not become inactive (strong restriction).
- Not just for threshold model—works for a wide range of contagion processes.
- We can analytically determine the entire time evolution, not just the final size.
- We can in fact determine $\Pr(\text{node of degree } k \text{ switching on at time } t)$.
- Asynchronous updating can be handled too.

Cascade window—summary

For our simple model of a uniform threshold:

- Low $\langle k \rangle$: No cascades in poorly connected networks. No global clusters of any kind.
- High $\langle k \rangle$: Giant component exists but not enough vulnerables.
- Intermediate $\langle k \rangle$: Global cluster of vulnerables exists. Cascades are possible in "Cascade window."

Expected size of spread

Expected size of spread

Pleasantness:

- Taking off from a single seed story is about **expansion** away from a node.
- Extent of spreading story is about **contraction** at a node.

Threshold contagion on random networks

- Next:** Find expected fractional size of spread.
- Not obvious even for uniform threshold problem.
- Difficulty is in figuring out if and when nodes that need ≥ 2 hits switch on.
- Problem **beautifully solved** for infinite seed case by Gleeson and Cahalane: "Seed size strongly affects cascades on random networks," Phys. Rev. E, 2007. [14]
- Developed further by Gleeson in "Cascades on correlated and modular random networks," Phys. Rev. E, 2008. [13]

Expected size of spread

Expected size of spread

- Notation:** $\phi_{k,t} = \Pr(\text{a degree } k \text{ node is active at time } t)$.
- Notation:** $B_{kj} = \Pr(\text{a degree } k \text{ node becomes active if } j \text{ neighbors are active})$.
- Our starting point: $\phi_{k,0} = \phi_0$.
- $\binom{k}{j} \phi_0^j (1 - \phi_0)^{k-j} = \Pr(j \text{ of a degree } k \text{ node's neighbors were seeded at time } t = 0)$.
- Probability a degree k node was a seed at $t = 0$ is ϕ_0 (as above).
- Probability a degree k node was not a seed at $t = 0$ is $(1 - \phi_0)$.
- Combining everything, we have:

$$\phi_{k,1} = \phi_0 + (1 - \phi_0) \sum_{j=0}^k \binom{k}{j} \phi_0^j (1 - \phi_0)^{k-j} B_{kj}.$$

For general t , we need to know the probability an edge coming into a degree k node at time t is active.

Notation: call this probability θ_t .

We already know $\theta_0 = \phi_0$.

Story analogous to $t = 1$ case. For node i :

$$\phi_{i,t+1} = \phi_0 + (1 - \phi_0) \sum_{j=0}^{k_i} \binom{k_i}{j} \theta_t^j (1 - \theta_t)^{k_i-j} B_{k_i,j}$$

Average over all nodes to obtain expression for ϕ_{t+1} :

$$\phi_{t+1} = \phi_0 + (1 - \phi_0) \sum_{k=0}^{\infty} P_k \sum_{j=0}^k \binom{k}{j} \theta_t^j (1 - \theta_t)^{k-j} B_{k,j}$$

So we need to compute $\theta_t \dots$ massive excitement...

Expected size of spread

Iterative map for θ_t is key:

$$\theta_{t+1} = \underbrace{\phi_0 + (1 - \phi_0) \sum_{k=1}^{\infty} \frac{k P_k}{\langle k \rangle} \sum_{j=0}^{k-1} \binom{k-1}{j} \theta_t^j (1 - \theta_t)^{k-1-j} B_{k,j}}_{\text{social effects}} = G(\theta_t; \phi_0)$$

Expected size of spread

First connect θ_0 to θ_1 :

$\theta_1 = \phi_0 +$

$$(1 - \phi_0) \sum_{k=1}^{\infty} \frac{k P_k}{\langle k \rangle} \sum_{j=0}^{k-1} \binom{k-1}{j} \theta_0^j (1 - \theta_0)^{k-1-j} B_{k,j}$$

$\frac{k P_k}{\langle k \rangle} = R_k = \mathbf{Pr}$ (edge connects to a degree k node).

$\sum_{j=0}^{k-1}$ piece gives \mathbf{Pr} (degree node k activates) of its neighbors $k - 1$ incoming neighbors are active.

ϕ_0 and $(1 - \phi_0)$ terms account for state of node at time $t = 0$.

See this all generalizes to give θ_{t+1} in terms of $\theta_t \dots$

Expected size of spread:

Retrieve cascade condition for spreading from a single seed in limit $\phi_0 \rightarrow 0$.

Depends on map $\theta_{t+1} = G(\theta_t; \phi_0)$.

First: if self-starters are present, some activation is assured:

$$G(0; \phi_0) = \sum_{k=1}^{\infty} \frac{k P_k}{\langle k \rangle} \bullet B_{k,0} > 0.$$

meaning $B_{k,0} > 0$ for at least one value of $k \geq 1$.

If $\theta = 0$ is a fixed point of G (i.e., $G(0; \phi_0) = 0$) then spreading occurs if

$$G'(0; \phi_0) = \sum_{k=0}^{\infty} \frac{k P_k}{\langle k \rangle} \bullet (k - 1) \bullet B_{k,1} > 1.$$

General fixed point story:

Given $\theta_0 (= \phi_0)$, θ_{∞} will be the nearest stable fixed point, either above or below.

n.b., adjacent fixed points must have opposite stability types.

Important: Actual form of G depends on ϕ_0 .

So choice of ϕ_0 dictates both G and starting point—can't start anywhere for a given G .

Expected size of spread

Two pieces: edges first, and then nodes

1. $\theta_{t+1} = \underbrace{\phi_0}_{\text{exogenous}}$

$$+ (1 - \phi_0) \underbrace{\sum_{k=1}^{\infty} \frac{k P_k}{\langle k \rangle} \sum_{j=0}^{k-1} \binom{k-1}{j} \theta_t^j (1 - \theta_t)^{k-1-j} B_{k,j}}_{\text{social effects}}$$

with $\theta_0 = \phi_0$.

2. $\phi_{t+1} =$

$$\underbrace{\phi_0}_{\text{exogenous}} + (1 - \phi_0) \underbrace{\sum_{k=0}^{\infty} P_k \sum_{j=0}^k \binom{k}{j} \theta_t^j (1 - \theta_t)^{k-j} B_{k,j}}_{\text{social effects}}$$

Expected size of spread:

In words:

If $G(0; \phi_0) > 0$, spreading must occur because some nodes turn on for free.

If G has an **unstable fixed point** at $\theta = 0$, then cascades are also always possible.

Non-vanishing seed case:

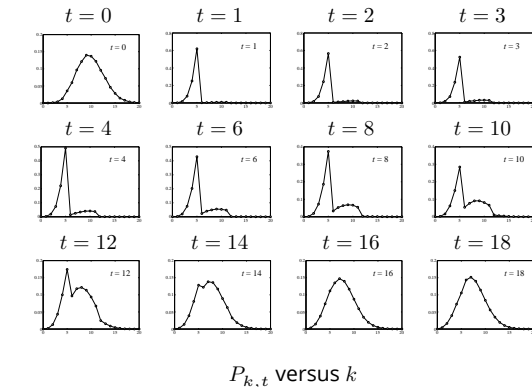

Cascade condition is more complicated for $\phi_0 > 0$.

If G has a **stable fixed point** at $\theta = 0$, and an **unstable fixed point** for some $0 < \theta_* < 1$, then for $\theta_0 > \theta_*$, spreading takes off.

Tricky point: G depends on ϕ_0 , so as we change ϕ_0 , we also change G .

A version of a critical mass model again.

Early adopters—degree distributions

$P_{k,t}$ versus k

Expected size of spread

Exploration of threshold model of social contagion on various networks.

"Influentials" are limited in power.

Connected groups of weakly influential-vulnerable individuals are key.

Average individuals can have more power than well connected ones.

The multiplier effect:

- Fairly uniform levels of individual influence.
- Multiplier effect is mostly below 1.

Extensions

- Assumption of sparse interactions is good
- Degree distribution is (generally) key to a network's function
- Still, random networks don't represent all networks
- Major element missing: **group structure**

Assortativity in group-based networks

- The most connected nodes aren't always the most 'influential.'
- Degree assortativity is the reason.

Social contagion

"Without followers, evil cannot spread." -Leonard Nimoy

Summary

- 'Influential vulnerables' are key to spread.
- Early adopters are mostly vulnerables.
- Vulnerable nodes important but not necessary.
- Groups may greatly facilitate spread.
- Seems that cascade condition is a global one.
- Most extreme/unexpected cascades occur in highly connected networks
- 'Influentials' are posterior constructs.
- Many potential influentials exist.

Social contagion

Implications

- Focus on the influential vulnerables.
- Create entities that can be transmitted successfully through many individuals rather than broadcast from one 'influential.'
- Only simple ideas can spread by word-of-mouth. (Idea of opinion leaders spreads well...)
- Want enough individuals who will adopt and display.
- Displaying can be passive = free (fashion), or active = harder to achieve (political messages; even so: buttons and hats).
- Entities can be novel or designed to combine with others, e.g. block another one.
